Wind Electricity Subsidies = Windfall Gains for Land Owners?

Evidence from a Feed-In Tariff in Germany

Wind electricity subsidies = Windfall gains for land owners? Evidence from a feed-in tariff in Germany

Peter Haan* Martin Simmler[†]

Abstract

In 2013, around 121 billion US-Dollar were spend worldwide to promote the investment into renewable energy sources. The most prominent support scheme employed is a feed-in tariff, which guarantees a fixed price for electricity produced by renewable energies sources, usually for around 15 years after the installation of the plant. We study the incidence of wind turbine subsidies, due to a feed-in tariff in Germany, into land prices to shed light on who benefits from the subsidies. In order to identify the incidence share we exploit quasi-experimental variation in wind strength across 270 non-urban counties combined with an institutional reform and use an Instrumental Variable estimator based on administrative transaction prices. We find that between 15 and 20% of expected wind turbine profits are capitalized into land prices. Using the estimated incidence share of 15%, we find that wind turbine subsidies account for roughly 4% of overall agricultural income of land owners in 2007.

JEL Classification: H22, H23, H25, Q28, Q42.

Keywords: Incidence, subsidy, renewable energy, wind turbines, land prices.

1 Introduction

Most countries subsidize investment into renewable energy sources (RES) as increasing the usage of RES for electricity production is seen as key to alleviate the trend in global warming in recent decades. Taking together all the various support schemes around the world, the International Energy Agency estimates that around US\$ 121 billion (100 billion euros) were spent in 2013 to promote green energy (International Energy Agency (2014)).¹ Spending was in particular high in the European member states, coming to a total of 40 billion euros (Alberici et al. (2014)). These enormous amounts raise concerns about the distributional consequences and the efficiency of the subsidies. In particular it is of central importance to understand who receives the subsidies. Is it the investor; and consequently does the subsidy ensure that green electricity plants are profitable? Or to what extent do other market participants – such as, for example land owners – benefit from the subsidy as windfall gains? The aim of this paper is to provide empirical evidence on this incidence question. To identify the incidence share we exploit quasi-experimental variation in wind strength combined with an institutional reform and use an Instrumental Variable estimator based on administrative transaction prices.

In more detail, in the analysis, we focus on the incidence effect of onshore wind turbine subsidies in Germany. The incidence effects are studied in the context of agricultural land prices. In addition we analyse the consequences of the subsidy on agricultural land owners' income. The setting in Germany is in particular suitable for our analysis. First, RES subsidies are important. In 2012, about 12 billion euros were spent on these subsidies, the rough equivalent of 20% of Germany's tax revenue on corporate profits. Second, Germany uses a very common policy measure to foster the investment into RES, which is a feed-in tariff. This support scheme has now been introduced in over 60 countries (Requate (2014)).² The central mechanism is a guarantee for a fixed wholesale price for electricity produced by RES for usually 15 to 20 years after the installation of the plant. Germany was one of the first countries to introduce this rule when it adopted the Renewable Energy Act (REA) in 2000. Third, descriptive evidence based on aggregate statistics suggests that the REA had a sizeable impact on the energy market. Following the introduction of the REA, electricity produced by RES as a share of overall electricity consumption increased

¹The estimate bases on a survey of established national policies and of deployment of new capacity by the IEA.

²Other measures include for example investment grants, quotes and tenders. See Klessmann et al. (2011) for an overview of measures used by different EU countries.

from 6.2% in 2000 to 23.7% in 2012. More than half of the overall electricity generated by RES came from onshore wind turbines.³ Finally, land owners and investors are likely to be the main beneficiaries of the subsidy for wind turbines as there is no labour involved in the electricity generation using wind turbines.

In order to empirically evaluate the incidence of the subsidy we exploit quasi-experimental variation related to large regional variation in wind strength in combination with the introduction of the REA. In the empirical specification we estimate the effect of the potential future income streams related to wind turbines in a particular county on the average land price in that county. The specification is motivated by Titman's work on the price of vacant land under uncertainty (Titman, 1985) which suggests that the price for each field on which a wind turbine can potentially be built increases with the subsidy.

Our identification strategy allows to estimate the causal effect of the potential future income stream of wind turbines on the land price. In particular, we use an Instrumental Variable estimator and investigate to which extent wind turbine investors receive the subsidy and to which extent the subsidy affects transaction prices for agricultural land and is therefore passed through to land owners.⁴ To ensure unbiased coefficients it is crucial to account for the measurement error in the expected potential future income streams, which have to be modelled as they are not observed. Therefore, we instrument the net present value of the potential future income streams generated by wind turbines in a particular county using regional variation in wind strength across over 270 non-urban counties in combination with the introduction of the REA. Then we estimate the effect on the average land price in the counties.

The results suggest that on average between 15 and 20% of expected wind turbine profits are capitalized into land prices. The results are robust across a wide range of specifications. In particular, they are not sensitive to the inclusion of different regional time trends or if we account for spatial dependence of land prices. Based on an investors' costs share of roughly 50%, our findings suggest that on average between 7.5 and 10% of the subsidy are captured in land prices. The estimated incidence share translates - based on 2010 values - into capitalized

³Source: Federal Ministry for Economics and Energy 2015, available online at http://www.erneuerbare-energien.de/EE/Redaktion/DE/Downloads/zeitreihen-zur-entwicklung-der-erneuerbaren-energien-in-deutschland-1990-2014.pdf?__blob=publicationFile&v=4, last accessed: 17/12/2015

⁴We focus on agricultural land as this is the main building ground for wind turbines due to a required minimum distance to population areas.

wind turbine subsidies of 4,400 euros per hectare of land or 27% of the average land price per hectare. Using the estimated incidence share of 15% and taking into account the characteristics of the German agricultural land market (e.g. share of sold and leased land and amount of sold land every year), we calculate that wind turbine subsidies increase overall agricultural income of land owners by about 4%. We validate the increase in agricultural income as well as our estimated incidence share by using a different data set, namely agricultural income tax data between 1998 and 2007. Using a simple fixed-effects regression analysis at the county level, we show that agricultural income observed in the tax data rises by our calculated additional taxable income resulting from wind turbine subsidies between 1998 and 2007.

Our paper contributes to the prior literature in several ways. First, we estimate the incidence of a subsidy for wind energy into agricultural land prices. In general the production of wind energy is unrelated to the agricultural value of land, but has a measurable impact on agricultural land price. In quantitative terms, the estimated incidence share is at the lower end of estimates for agricultural subsidies.⁵ Kirwan (2009) estimates for the US an incidence share of 25%. Hendricks et al. (2012) suggests that the long run incidence in the US may be up to 40% as inertia in farmland rental rates and different types of tenancy agreements are likely to have biased prior estimates. This is similar to what has been found by Roberts et al. (2003). Ciaian and Kancs (2012) report that in the OECD countries around 20% of agricultural subsidies are reaped by land owners. Most comparable to our study is the work by Breustedt and Habermann (2011). They estimate an incidence share of 38% for agricultural subsidies for one region in Germany, namely the state of Lower Saxony.⁶

Second, we add to the literature that quantifies the distributional impact of environmental subsidies. Fullerton (2009) discusses six ways in which environmental policies (mainly taxation) may have distributional impact, which are all likely to be

⁵Similar results as for agricultural subsidies have been found for the incidence of the corporate income tax in the US (Suárez Serrato and Zidar, 2014).

⁶We suggest future demand to be the reason for the incidence share for RES subsidies to be lower than for agricultural subsidies but larger than zero. Appendix B shows that even with excess supply of land today land owners reap a seizable share of profits today if demand is expected to be high in the future. This is similar to the argument made by Sallee (2011), who analyses a subsidy for a new technology as well, hybrid cars, and finds that, despite a current excess demand, the entire surplus of the subsidy is reaped by the car buyers. Sallee suggests that manufacturers are not willing to increase the price due to the subsidy as this would hamper future demand. This suggests that the incidence for subsidies for established products is determined by the current market structure (e.g. Poterba (1996); Besley and Rosen (1999); Carbonnier (2007); Kirwan (2009)) and for new products by the expected market structure.

regressive. The empirical literature has confirmed this presumption for environmental taxes (Parry (2004); Metcalf (1999); Hassett et al. (2009); Grainger and Kolstad (2010)). The driving force behind the distributional impact of a carbon tax seem to be fuel and electricity use (Hassett et al. (2009)), or more precisely the fact that polluting goods are mostly energy intensive and account for a large share of the budget spend by low income households (Grainger and Kolstad (2010)). Metcalf (1999) suggests targeted tax cuts to make the policy distributionally neutral. The change in land prices is of minor importance in these studies as environmental taxes decrease pollution mainly due to abatement technologies. They thus do not consider renewable energies, which are location specific and thus likely to have distributional impact by changing land prices. More closely connected to our work is the study by Groesche and Schroeder (2014); they focus on photovoltaic plants on owner occupied houses and find that the German REA is mildly regressive.

Finally, our results add to the literature that discusses the efficiency of different policy instruments to promote renewable energies (e.g. Menanteau et al. (2003); Haas et al. (2011); Requate (2014)). Whether a price-based (such as a feed-in tariff) or a quantity based system (such as tradable green electricity certificates or quotes) should be preferred to foster investment into RES is often evaluated according to three dimensions: costs, installed capacity and technological development (see Menanteau et al. (2003)). Different distributional implications are not discussed although they are important and likely to differ.

The outline of the paper is as follows. Section two describes the relevant institutions and in particular the REA. The data is presented in section three, followed by the methodology in section four. Results on the incidence share are presented in section five, and on the distributional consequences of the wind turbine subsidies in section six. Section seven concludes.

2 Institutional Background

To alleviate the increase in global warming and to increase the share of RES to 20% in 2020 as agreed in the Kyoto Protocol and the Lisbon program, Germany introduced a technology specific feed-in tariff with the adoption of the Renewable Energy Act (REA) in 2000.⁷ This support scheme for RES seems to be the most

⁷Eichner and Runkel (2014) provide a rational for why countries subsidize renewable energy production instead of only taxing pollution. They study the optimal choice of the two in a multi-country, two-sector (clean and dirty production) framework with capital mobility and find that

prominent measure in the world as it has by now been adopted in over 60 countries (Requate (2014)). The REA in Germany replaced the Electricity Feed-in Act (EFA) and thus reduced investors' risk in two important dimensions. First, with respect to the wholesale price for energy, and second with respect to the length of time for which the price is paid. Under the EFA, which was a non technology specific feed-in tariff, the wholesale price for electricity was 90% of the end-consumer price and was only paid for as long as the law was in effect. Under the REA, a fixed technology-specific wholesale price is guaranteed for 20 years after the installation of the plant

The REA obliges utilities to accept the feed-in of green electricity from independent producers into their grid and to remunerate it at a given price. The costs of the subsidy, which equal the difference between the wholesale market price of electricity and the feed-in tariff, are born by almost all electricity consumers.⁸ They pay a share of their electricity bill into a fund from which the costs of the utilities are reimbursed. If the costs of the subsidy increase, the share of the electricity bill is adjusted. In 2013, the direct costs of the subsidy amount to roughly 20% of the average electricity bill (Neuhoff et al. (2012)).

The feed-in tariff guaranteed by the REA depends on the RES used for the production.⁹ The wholesale price for wind electricity over the life time of the plant is determined by three parameters, two tariffs (high and low) and a parameter which determines the duration of the high tariff.¹⁰ The two tariffs decreased relatively steadily from 9.1 and 6.19 cent per kWh in 2000 to 9.02 and 4.92 cent per kWh in 2012 due to reforms and degression rates included in the REA (see Table 1). The parameter governing the duration of the high tariff increased from 0.75 to 0.85 between the years 2005 and 2008. The most significant change in the feed-in tariff after its introduction was implemented with a reform of the REA in 2009. Unproductive wind turbines with less than 60% of the reference plant return did not longer receive the subsidy. This implied a partial abolition of the promotion scheme

subsidizing RES reduces the overall distortion of the tax-subsidy system.

⁸Reductions are granted to energy intensive companies. This has been investigated by the European Commission and has been found to be in line with state aid rules (http://europa.eu/rapid/press-release_IP-14-2122_en.htm).

⁹For photovoltaics the tariff according to the REA 2000 was the highest with 48.1 cent per kWh, for water energy it amounted to 7.67 cent per kWh.

¹⁰This period is at least 5 years but in most cases considerably longer as it is extended if the wind turbine has a lower productivity compared to a reference plant defined in the law. For the reference plant defined in the law, the first, higher tariff is for example paid 16 years. See Appendix C for further details.

for certain areas. Despite the reduction in the feed-in tariff, the return of newly built wind power plants increased over time remarkably due to the technological development of wind turbines, see Figure 1.¹¹

Table 1: Feed-in Tariff for Wind Energy

Year	Tariff 1	Factor for time period calculation for tariff 1	Tariff 2	Minimum return	Guaranteed time period in years
1991-1999	90% of the consumer electricity price				none
2000	9.10	0.75	6.19		20
2001	9.10	0.75	6.19		20
2002	8.96	0.75	6.10		20
2003	8.83	0.75	6.01		20
2004	8.70	0.75	5.92		20
2005	8.70	0.85	5.50		20
2006	8.70	0.85	5.50		20
2007	8.70	0.85	5.50		20
2008	8.53	0.85	5.39		20
2009	9.2	0.75	5.02	60%	20
2010	9.2	0.75	5.02	60%	20
2011	9.11	0.75	4.97	60%	20
2012	9.02	0.75	4.92	60%	20

Note: Tariff 1 is paid for at least five years. The time period is extended if the return of the wind turbine is lower than the return of a reference plant. See Appendix C for further details.

3 Data and Descriptive Statistics

To investigate the effect of the subsidy for wind electricity on transaction prices for agricultural land, we use three different sets of variables in our empirical analysis: i) transaction prices for agricultural land, ii) the net present value of expected wind turbines profits, and iii), variables that capture the return of agricultural land and the demand for agricultural products. Since transaction prices are only observed on the county level, we aggregate all other variables and use averages on the county level.

Transaction prices: Our sample for the empirical analysis includes all non-urban counties in Germany for which transaction prices are available between 1997 and 2012 and without any changes in their administrative boundaries.¹² The in-

¹¹The average installed capacity of a single wind turbine doubled between 1995 and 2010, mainly related to higher plant size and larger rotor calibres (see Figure A.1). See Johnstone et al. (2010) for an empirical analysis on the impact of RES support schemes on technological development.

¹²Counties in Thuringia are only included from 2004 onwards due to missing information before

Figure 1: Evolution Wind Turbine Profitability

Notes: Evolution of expected wind turbine profitability for two different average wind strengths are shown. P50 stands for the median, P75 for the 75th percentile. The profitability of a wind turbine in a current year is calculated as expected income over costs using the latest available technology. The latest available technology is based on the average technology of wind turbines built in a current year. For more details on the calculation of expected income and costs see Appendix C.

Source: Author's calculations based on data of the German Weather Service and operator database 1999-2012.

formation on average transaction prices for agricultural land at the county level for the period between 1997 and 2012 are obtained from the publications of the Federal Statistical Offices of the German states. We focus on transaction prices for agricultural land as this is the main building ground for wind turbines due to a required minimum distance to population areas. To ensure that the transaction prices are representative on a county level, we exclude counties for which less than 10 transactions occurred within a year.¹³ Thus overall the analysis is based on an unbalanced panel for 1997 to 2012 with around 270 counties and 4,107 county-year observations.¹⁴ The counties covered in our sample account for about 80% of the installed capacity of wind turbines and the number of turbines in Germany (see Table A.1, Appendix A)

Net present value of expected wind turbine profits: The net present value of expected wind turbine profits in one county is constructed in several steps

that time. For the same reasons, counties in Schleswig-Holstein, North Rhine Westphalia and Bavaria are not included for the year 1997. Due to two changes in the administrative boundaries during the time period studied, counties in Sachsen-Anhalt are not in the sample.

¹³Further, we dropped counties in which the absolute value of the growth rate of the transaction price was below the 1% or above the 99% percentile to avoid that outliers drive the results.

¹⁴Results are not significantly different if we use a (un)balanced panel for 1998 to 2010.

using the following data sources: a) Information on the technological details of all wind turbines in Germany from the operator database¹⁵, b) Information on the (1981 to 2000) average wind strength on a square kilometre raster 10 and 80 metre above the ground provided by the German Weather Service¹⁶, c) information from the financial statements database DAFNE about the financing of wind turbines and the calculation of the depreciation allowances for the turbines, and d) information on the regional share of suitable agricultural land to build wind turbines from the German Environmental Agency (2013).

We calculate the profits of an average technology wind turbine per hectare for each German county and year.¹⁷ First, we calculate the produced energy of the representative county-year wind turbine using the mean characteristics of wind turbines built in a particular year and the average wind strength in the county. Second, based on the feed-in tariff that applied in a particular year and the expected electricity generated of the plant, we derive the expected income streams and discount them using a discount rate of 3%.¹⁸ Third, expected investment and finance (including equity) costs are deducted. Investment costs are approximated based on installed capacity. The share of bank financing, maturity and interest rate are based on descriptive statistics in DAFNE. Fourth, we derive the expected net present value of wind turbine profits per hectare by dividing profits through the amount of land used. The land usage accounts for the baseplate as well as the minimum distance to the next wind turbine which is determined by law. We approximate the required minimum distance based on the published ratio of installed capacity to minimum distance, which is 6 hectare per MW (German Environmental Agency (2013)). Finally, we scale the county-year representative net present value of profits per hectare with the regional share of suitable land to build wind turbines published by the German Environmental Agency (2013) to account for the fact that turbines

¹⁵Although the database is private (<http://www.betreiber-datenbasis.de/>) it covers all wind turbines in Germany. To assess the representativeness we compared the reported number of plants and installed capacity with information published by the network operators (<https://www.netztransparenz.de/de/Anlagenstammdaten.htm>). The latter is a publicly available database but contains no information on wind turbine's technology.

¹⁶We mapped the data to German county level by first mapping it to the municipality level and then constructing a weighted average on the county level using the agricultural land within the municipalities as weighting factor.

¹⁷A detailed description can be found in Appendix C. Descriptive statistics based on wind turbine firms are reported in Appendix D.

¹⁸For wind turbines built before the REA was introduced we assume that investors expected to receive the guaranteed price of 90% of the end-consumer price for three years after the installation of the plant, afterwards we assume that investors expected the on average market price for electricity of 3 cent per kWh.

Figure 2: NPV Wind Turbine Profits per Hectare in 1998

Notes: The net present value of expected wind turbine profits per hectare for each German county in 1998 is shown. For more details see the description in the text.

cannot legally be built on all agricultural land.¹⁹ The resulting net present value of wind turbine profits per hectare in each county in Germany in 1998 and 2002 is shown in Figure 2 and Figure 3, respectively. The figures suggest a remarkable cross-sectional as well as time-series variation due to the introduction of the REA.

Variables capturing the agricultural value of land: In the analysis we include a variety of indicators that determine the price of land in addition to potential profits of wind turbines. The data is provided by the Federal Statistical Office. In particular we include: share of farmland or of grassland (base category: permanent crop); the share of cereal, root crop or forage crop (base category: trade plants); the harvest per hectare wheat, potatoes and silo corn; and the share of land used by farms with stock breeding. In addition we include variables which capture the impact of urban proximity. Namely, we control for the population and the population density (population divided by area size), the average wage income, the rate of unemployment the average property tax on agricultural land, the average business tax and the property transfer tax within the county. Finally, we include

¹⁹We take the legal constraint as given, although market participants might have expected changes.

the inverse distance weighted average of the population in neighbouring counties.²⁰

Descriptive statistics for all variables are shown in Table 2. The average transaction price is 17.100 euros, the expected net present value of wind turbine profits amounts to 21.200 euros per hectare, the expected net present value of wind turbine revenues amounts to 38.900 euros per hectare.

4 Methodology

4.1 Estimation Equation

In the following we present the empirical strategy for the analysis of the incidence effects of the REA. As mentioned above, we observe land prices per hectare not on the field level but on the county level j . Thus we estimate the effect of the net present value of expected profits per hectare $WR_{j,t}$ and the agricultural return $AR_{j,t}$ on the land price $LP_{j,t}$ on the county level; $\omega_{j,t}$ is an i.i.d. distributed error term.²¹

$$LP_{j,t} = a_j + \alpha WR_{j,t} + \gamma AR_{j,t} + \omega_{j,t} \quad (1)$$

For the interpretation of the incidence effect two points are important to note. First, we assume that wind turbines do not affect the agricultural return of land. Thus, investors do not have to compensate land owners for a loss in agricultural production if a turbine is built. This assumption is plausible as the size of the baseplate of a wind turbine is very small. The relationship between profits and the share reaped by land owners is thus independent of the agricultural return, i.e. $WR_{j,t}$ and $AR_{j,t}$ are not correlated.

Second, land prices of suitable fields are affected independent of whether a turbine has been built on a field during our sample period or not. Titman (1985) shows that expectations about future demand, and thus land prices in the future, are

²⁰In a robustness check, we account also for a potential spatial dependence of agricultural land prices by including the inverse distance weighted average transaction price in neighbouring counties. To address the endogeneity of this variable, we employ an instrumental variable approach. The choice of our instrument follows the approach used for our main explanatory variable.

²¹In order to interpret the coefficient α as the incidence share of the subsidies we focus only on the fraction of land that can be used to build wind turbines when calculating $WR_{j,t}$. As explained in section 3, we observe the regional share of land on which turbines can legally be built: based on this information we adjust the net present value of wind turbine profits per county.

Table 2: Descriptive Statistics

Variable	N	Mean	P25	P50	P75	SD
Land price ph in euro	4,107	17,087	8,567	14,625	23,659	11393

included in the land price today. Land owners will ask, therefore, for compensation if they sell their suitable land to non-investors, as the new owner may sell the land to an investor in the future. Since there is only one market price for a particular type of land, the price of land is independent of whether the land is bought by an investor (and thus a turbine is built) or by a non-investor (and no turbine is built). Thus, even if no turbines would have been build in our sample period, α would be larger than zero if land owners expect with a non-zero probability that turbines will be built in the future. For a more formal analysis of this argument see Appendix B.

4.2 Estimation Strategy

The main reason why an OLS estimate for the parameter of interest α in equation (1) will be biased is measurement error.²² We do not observe the true net present value of expected wind turbine profits per hectare in a county; instead we approximate the expected wind turbine profits with the profits of an average technology wind turbine per hectare in a particular county and year adjusted with the regional share of (legally) suitable land. Therefore, the net present value of expected profits is subject to measurement error which we need to take into account in the estimation. Our specification does, however, not suffer from the endogeneity of the location decision since we do not use the average profits of installed wind turbines and/or the share of land chosen to build wind turbines.

Our identification strategy accounts for the measurement error and allows us to estimate the causal effect of the potential income stream on the land price. In particular, we use an Instrumental Variable estimator and instrument the net present value of the potential future income streams generated by wind turbines in a particular county using regional variation in wind strength across over 270 non-urban counties in combination with the introduction of the REA. In more detail, we use a difference-in-differences (DiD) strategy as an instrument in the first stage. We define the treatment and control groups based on the average wind strength in a county as this is a strong predictor for wind turbine profitability; hence we

²²Another thread to our estimation strategy, which would not only bias the OLS but also any other estimator, is a systematic change in the composition of the transacted land due to wind turbine subsidies. In other words, it is required that wind turbine investors are indifferent between buying agricultural land and leasing it only. If they are not indifferent, the composition of the transacted land would change over time non randomly and thus limit comparability over time. Using the IV strategy as outlined in this section, we assessed whether the number of transactions, the size of sold land and the quality of sold land changed in response to the introduction of the subsidy. We do not find evidence for that. Results are available upon request from the authors.

Figure 4: Average Wind Strength in m/s

exploit that the treatment counties were affected by the introduction of the REA with a higher intensity than those counties with a low wind strength, i.e. the control counties.

In Figure 4, we document that the wind strength varies substantially between German counties. Although it is clear that the wind strength is in particular high near the coast, it is also much higher in the middle of Germany and higher in the western part of the north compared to the eastern part. This suggests that the variation in wind strength is largely independent of other regional variation in particular between states. This allows us to include linear and quadratic state-specific time trends in the regression to capture any other state specific trends in land prices. Further, it is unlikely that the wind strength is correlated with idiosyncratic county characteristics which are the reason for the measurement error in the net present value of profits.²³

In one of the main specifications we define counties with wind strength above

²³Examples for idiosyncratic county characteristics are the preference of the population for wind energy (which may pressure politicians and so result in the delayed issuance of building permits), the distribution of population areas or nature protection areas and agricultural land within the county (which affects the share of suitable land within a county) or the density of the electricity network (which is important as the wind turbine investor has to pay for the connection to the grid).

the median as the treatment group and the other counties as control groups.²⁴ Further, we propose to exploit even more of the variation for our instrument. In an additional specification we construct a treatment intensity variable, which is defined as the average wind strength in a particular county instead of splitting the sample in treatment and control groups. The treatment (intensity) variable is then interacted with a reform dummy for years after the introduction of the REA.

More formally, in the first stage we regress the net present value of expected wind turbines profits in a county ($WR_{j,t}$) on the instrument ($WS_{j,t} * D(> 1999)$), a post-treatment indicator ($D(> 1999)$) and the control variables ($AR_{j,t}$) which capture the agricultural return of land (see equation (2)). The results of the first stage regression indicate that our instrument is highly relevant and explains roughly 2/3 of the variation in the net present value of wind turbine profits (see Table A.2, Appendix A).

$$WR_{j,t} = a + a_1 WS_{j,t} + a_2 WS_{j,t} * D(> 1999) + a_3 D(> 1999) + a_4 AR_{j,t} + u_{j,t} \quad (2)$$

In the second stage of our approach we then regress the average transaction price of land on the predicted net present value of wind turbine profits ($\hat{WR}_{i,t}$) in the county and the controls.

$$LP_{j,t} = c + \alpha AR_{j,t} + \alpha_1 \hat{WR}_{j,t} + \omega_{j,t} \quad (3)$$

An important underlying assumption for our identification strategy is the common trend between the treatment and the control group. In other words, the transaction prices for land in the treatment and control group should behave similar in the absence of the introduction of the REA. To assess the plausibility of this assumption, Table 3 reports descriptive statistics in 1999 for the treatment and control group based on median wind strength. Further, Figure 5 shows the evolution of land prices between 1998 and 2010 for the two groups.²⁵

The descriptive statistics for the treatment and control groups suggest differences in the agricultural return of land and in the land usage for the two groups (see Table 3). Regarding population, population density, income, and the local business

²⁴Our results are not sensitive to this choice. They are almost unchanged when using the mean or the 75th percentile for the classification instead. Results are available upon request from the authors.

²⁵We only include 1998 to 2010, as for 1997, 2011 and 2012 the number of observations is much smaller than for 1998 to 2010.

Table 3: Descriptive Statistics Treatment and Control Group 1999

Variable	Treatment Group		Control Group		p-value
	Mean	SD	Mean	SD	t-test

log(Distance weighted population)	12.9	3	14.3	2.5	0
Population density	4.74	5.41	5.79	6.24	0.15
Average wage income per month in euro	1,977	1,328	1,968	1,382	0.96
Unemployment rate	0.09	0.04	0.07	0.03	0
<i>Tax variables:</i>					
Property tax on agricultural land	258	53	294	55	0
Property transfer tax	3.5	0	3.5	0	1
Local business tax	327	48	323	40	0.45

Notes: Treatment group includes counties with wind strength 80 metre above ground above the median. Control group includes counties with wind strength equal or below the median. Property tax on agricultural land is the average multiplier in the county. To derive the tax rate the multiplier has to be multiplied with 6%. Local business tax is the average local business tax multiplier in the county. To derive the tax rate the multiplier has to be multiplied with 0.05% before 2008 and 0.035% after 2007. ph stands for per hectare. In 1999 the property transfer tax was the same for all states in Germany.

tax rate no differences are observed. To control for potential differences in the levels we account for county-fixed effects and include in all specifications interaction effects with the agricultural return variables and a dummy for the introduction of the REA; the latter is to control for a different impact of the agricultural return variable on land prices after the the introduction of the REA. Finally, Figure 5 documents a common trend in the land prices before the introduction of the reform.

5 Estimation Results: Incidence Share

Main results: We present now the results of our main regression analysis (see Table 4). In the first two columns the OLS estimates with and without control variables are reported. The estimated coefficient is in both specification close to zero and statistically insignificant. As discussed above we suspect the OLS estimates to be biased and the main reason to be measurement error in the net present value of wind turbine profits (NPV WT profits). Column (3) to (6) present the IV results. In column (3) and (4) we use the interaction term between the treatment group based on median wind strength and the reform dummy, in column (5) and (6) the interaction between treatment intensity, e.g. the average wind strength in the

county, and the reform dummy as an excluded instrument.

Notes: Table shows estimated coefficients for the impact of the net present value of wind turbine profits per hectare on average land prices. WS stands for wind strength, and NPV WT profits ph for net present value of wind turbine profits per hectare. Column (1) and (2) are OLS estimates, (3) to (6) IV estimates. The excluded instrument in column (3) and (4) is the interaction between a treatment dummy which is one for counties with a wind strength above the median and a reform dummy for years after the introduction of the REA. In column (5) and (6) it is the interaction between the average wind strength 80m above ground on the county level and the reform dummy. Each regression includes a full set of county and time dummies (not reported.) Robust standard errors, clustered at the county level, in parentheses. Significance levels: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Source: Author's calculation based on data of the German Weather Service, operator Database 1990-2012, Statistik Lokal and Regional 1998-2012, Statistical Offices of the Laender 1997-2012.

The result in our most preferred specification shown in column (6) suggests that an increase of 1 euro in the net present value of wind turbine profits per hectare increases the price for land per hectare by 15 cents. In other words 15% of the net present value of wind turbine profits are reaped by land owners. The results are not significantly different if we use the treatment dummy instead of the intensity to construct our instrument (column (4)) or if we exclude our set of control variables (column (4)) or both (column (3)). Since profits may only be a small fraction of the overall subsidy paid, we calculate the capitalized amount as a share of the net present value of the expected subsidies. Based on the average costs share of roughly 50% in our sample (see Table 2), the incidence share is 7.5% when based on expected subsidy payments. Since the costs of wind turbines are mainly fixed costs, the incidence of a marginal increase in wind turbine subsidies by 1 euro is the same as for profits and amounts to 15 cents.

Our incidence estimate of 15% of the net present value of wind turbine profits

or 7.5% of the net present value of the wind turbine subsidies translates - based on 2010 values - into capitalized wind turbine subsidies of 4,400 euros per hectare of land. This amounts to an increase of 27% of the land price per hectare. Since only counties with high wind strength benefit from the subsidies, we calculate the impact of land prices for counties with a wind strength above the median. For these counties, the capitalized wind turbine subsidies amount to 6,800 euros per hectare or to 44% of the average land price per hectare.

The estimated coefficients for the control variables except for the year dummies, the state trends and the county-fixed effects are shown in Table A.3 and A.4 in Appendix A. Most of the control variables are insignificant. Exceptions are the harvest corn variables, interacted with the West Germany dummy and the reform dummy, which we include to control for a recent finding by Breustedt and Habermann (2011). Their result show that the introduction of subsidies for biogas plants with the REA lead to an increase in farmland rental rates in proportion to the share of land used for corn in West Germany but not in East Germany. Our results are in line with their results but are only marginally significant. More precisely estimated is the stream of income due to biogas plants per hectare in euro, which we included as well to control for the biogas subsidies paid.²⁶ The correlation is 0.2 between the subsidies received per hectare and the average land price per hectare. Urban proximity measured by the inverse distance weighted population in neighbouring counties and the population density increases land prices as suggested by prior literature (Livanis et al. (2006); Guiling et al. (2009)). Finally, the coefficients for the three tax variables are negative, but only statistically significant for the local business tax.

Sensitivity Analysis: We start assessing the sensitivity of our results by altering the way we calculate the net present value of wind turbine profits. First, we use instead of the regional share of suitable land to build wind turbines, the German average share, which is 14% (Table A.5 in Appendix A, column (1)). The point estimate increase slightly to 15.8%. In column (2) we use the net present value of wind turbine profits per hectare based on the profits of built wind turbines. The estimated coefficient increases to 20%. This increase is not surprising since our main measure is likely to overestimate the true net present value of wind turbine profits

²⁶The variable is derived by dividing the overall amount of subsidies for electricity generated by biogas plants by the installed capacity of biogas plants. Both variables stem from publications of the electricity network operators. We map the installed capacity of biogas plants to the county level to calculate the amount of subsidies for each county. Finally, the amount is scaled by the size of agricultural land.

(as it is based on the newest available technology) while the second measure is likely to be the lower bound (as it is based on the used technology in the past). Thus, we conclude that the incidence share is between 15 and 20%. The next robustness check concerns the Electricity Feed-in Act, which was in place up to 2000. In the baseline specification, we assumed investors to expect to receive the subsidy for up to 3 years, column (3) reports the results based on 5 years. The estimated coefficient increases but is still not significantly different from the baseline specification.

Further, we assess the sensitivity of our results with respect to differences between East and West Germany by including a different time trends for the two parts of Germany (Table A.6 in Appendix A, column (1)). This is motivated as a large share of agricultural land in East Germany before 2000 was held by the *Bodenverwertung- und Verwaltung GmbH (BVVG)* as in former East Germany agricultural land was collectively owned. The BVVG was founded to take over collectively owned land and to sell it with profit in the years after the reunification. Including a different time trend for West and East Germany has virtually no impact on the estimated coefficient. Moreover, we exclude counties with fewer than 100 transactions per year to assess whether small counties drive the results (Table A.6 in Appendix A, column (2)). Further, one might argue that prices based on fewer than 100 transactions are not representative. Again, the result is basically unchanged. Finally, we account for spatial dependence in transaction prices. Although our dependent variable is a county average transaction price and thus spatial dependence is likely to be of minor importance, it could still bias the results. In column (3) and (4) we include the inverse distance weighted transaction price of the neighbouring counties. Since the transaction price in neighboring counties is likely to be endogenous, we instrument the neighboring price in column (4) using the inverse distance weighted wind strength in combination with the introduction of the REA as instrument. The estimated coefficient decrease to 11%, but it is still significantly estimated and not different from the baseline specification. Thus, overall we conclude that our results are robust across the different specifications.

6 Impact of the Subsidies on Agricultural Land Owners' Income

In order to provide a deeper understanding of the result, in this section we use the estimated incidence share to study the impact of wind turbine subsidies on

agricultural land owners' income. To this end it is important to distinguish between turbines that are build on leased land and turbines that are build on (investors') own land, since in the first case land owners receive a yearly payment for 20 years whereas in the latter case land owners receive one non-recurring payment. Further, lease payments only increase if a turbine is built on the land, capital gains in contrast capture profits of wind turbines that may be built in the future as well.²⁷

In more detail, in order to assess the overall impact on agricultural income, we calculate the increase in lease payments and the additional capital gains resulting from wind turbine subsidies. The calculation is based on the following information: (i) the estimated incidence share of 15% (ii) the net present value of profits of wind turbines built (for the lease payments) and the net present value of profits of potential wind turbines (for the capital gains), (iii) the fraction of wind turbines built on leased land and (iv) the amount of sold land suitable to build wind turbines.

Since the proportion of wind turbines built on leased land (iii) and the amount of sold land suitable to build wind turbines (iv) are not observed, we approximate them in the following way: For the proportion of wind turbines built on leased land we use the share of land that is newly leased per year to the overall amount of land that is newly leased or sold per year. The underlying idea is that investors interested in a particular field cannot choose whether to buy or to lease the particular field of land as this is determined by the land owner. The share of newly leased to overall newly leased and sold land is around 82% in 2010 (German Federal Statistical Office (2011a,b)). The amount of sold land suitable for building wind turbines is derived by multiplying the amount of land sold in a particular county and year (which is observed in the data) with the share of suitable land in that county (obtained from the German Enviromental Agency (2013)).

Lease payments: As a first step we calculate the lease payment for each wind turbine built in Germany. We assume that this is the yearly amount paid for 20 years, which is equivalent to 15% (our incidence share) of the net present value of profits of the plant.²⁸ The single lease payments are then aggregated for all plants within a county in a particular year. Since not all wind turbines have been built on leased land, we scaled the overall amount of lease payments in each county and year

²⁷This is in line with one of the explanations proposed by Grainger (2012) why housing values react more strongly than rents to (current) improvements in air quality. If current improvements increase the likelihood of future improvements in air quality, house prices should respond stronger than rents as future improvements are only priced by sellers and buyers. Renters pay only for current air quality.

²⁸The calculation is based on the following standard annuity formula and a discount rate of 3%:
 $lease_i = NPVWT_i * (1.03^{20} * 0.03) / (1.03^{20} - 1).$

with the share of wind turbines built on leased land, which is 82%.

Capital gains of land owners: Capital gains are calculated by multiplying the expected increase in the price per hectare due to the subsidy with the amount of sold land in a county suitable to build wind turbines. The expected increase in the price per hectare stems from our empirical results (see Table 4) and equals to 15% of the net present value of expected wind turbine profits per hectare.

In our estimation sample, the average amount of wind turbine subsidies received by all owners of land within one county is 1.6 million euros (see Table 5). For the year 2010 (2007), the overall amount is slightly higher with 2.2 (1.9) million euros. On average 1/3 of the additional income is due to lease payments and 2/3 due to capital gains. These shares do not vary much over time. To put these numbers into perspective, we relate them to the overall income that arises from agricultural land. Since agricultural land income is not separately reported for incorporated firms, we focus on West Germany for the comparison as in this part of Germany 99% of all agricultural land is owned by individuals or partnerships (German Federal Statistical Office (2011b)).²⁹ For these land owners, we observe agricultural income in the income tax data. For the comparison we use the latest year available, which is 2007.³⁰ As in our main analysis, we aggregate the agricultural income on the county level. Based on the income tax statistic, the additional income due to wind turbines that results from our calculation described above amounts to 4.3% of the average agricultural income in 2007 (see Table 5). When considering only counties with a wind strength above the median (above the 75 percentile), the share increases to 6.6% (8.2%). Wind turbine subsidies thus have a measurable impact on agricultural land owners' income.

Besides shedding light on the relative importance of wind turbine subsidies for agricultural land owners' income, we further exploit the income tax data to validate our analysis. In particular, if our estimation is correct, agricultural income should over time exactly increase by the estimated additional income - holding all our factors constant. We test this using a simple regression analysis framework. Since the income tax is also available for 1998, 2001 and 2004, we construct a county-year level panel that covers all West German counties that are included in the main analysis.³¹ The dependent variable is the overall agricultural income in a particular

²⁹The fraction in East Germany is only 50%. Further, a huge share of land in East Germany is owned by the BVVG.

³⁰The data is a stratified sample of the almost 40 million taxpayers in Germany.

³¹Results are unchanged when including all West German, non-urban counties, independent whether they are included in the main estimation sample or not.

Table 5: Quantification Impact on Agricultural Land Owners' Income

Sample	N	Million hectare of land	Agric. Income	Wind turbine income		
				Lease payments in million euro	Capital gains	Overall in %
Sample period 1997-2012	4,107			0.4	1.2	
Sample period 2010	274	14.5		0.7	1.5	
Sample period 2007	272	14.6		0.6	1.3	
West Germany 2007	221	10.4	34.7	0.6	0.9	4.3
West Germany 2007, WS > P50	106	5.6	38.1	1	1.5	6.6
West Germany 2007, WS > P75	56	3.6	47.4	1.6	2.3	8.2

Notes: WS stands for wind strength, P50 for the median and P75 for the 75th percentile.

Source: Author's calculation based on data of the German Weather Service, income tax statistic 1998, 2001, 2004, 2007, operator database 1990-2012, Statistik Lokal and Regional 1998-2012.

county and year. The main explanatory variable is our calculated additional income due to wind turbine subsidies. We further control for the return of agricultural land, the demand for agricultural products, the tax burden on land and state specific linear and quadratic time trends as in our main specification.³² Descriptive statistics for the sample are shown in Table A.7 in Appendix A.

The regression results are shown in Table 6. Column (1) shows the results without including any control variables, column (2) with the inclusion of the control variables. In column (2) the point estimates is 1.096, significant at the 5% level and clearly not statistically different from one. In column (3) we use the simulated increase in taxable income based on an incidence share of 20%, which gives us an estimated coefficient of 0.822, again significant at the 5% level and not different from one.

7 Conclusions

In this paper, we estimate the incidence of wind turbine subsidies into land prices exploiting regional variation in wind strength across counties in combination with the introduction of the REA for identification. Our results suggest that on average land owners reap between 7.5 and 10% of the expected potential net present value

³²The variables capturing the agricultural return of land are not measured as share but as the actual amount of land. Further, to avoid biased results due to reversed causality, we use the 1998 land usage and interact the variables with year dummies. Due to the interaction with the year dummies, we control again for a potential different impact of land usage after the introduction of the REA as well a average changes in land usage. Due to multicollinearity problems we do not include the amount of grassland but only the amount of farmland.

Notes: Table shows estimated coefficients for the impact of calculated income due to wind turbine subsidies on agricultural income on a county level. Sample includes all counties in West Germany in 1998, 2001, 2004 and 2007, which are included in our main estimation sample. Each regression includes a full set of county and time dummies (not reported.) Robust standard errors, clustered at the county level, in parentheses. Significance levels: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Source: Author's calculation based on data of the German Weather Service, income tax statistic 1998, 2001, 2004, 2007, operator database 1990-2007, Statistik Lokal and Regional 1998-2007.

of the subsidy or between 15 and 20% of the expected potential net present value of wind turbine profits. Based on these results, we calculate that in counties with a wind strength above the 75th percentile, wind turbine subsidies account for more than 8% of agricultural income in 2007.

The implications of our study are at least twofold. First, renewable energies subsidies based on a feed-in tariff are likely to generate windfalls profits for land owners, although the magnitude depends on the cost curve of investors. To minimize the resulting impact of RES subsidies on the income distribution, which is increasing in the share of sold land every year, land taxes may be used to finance the subsidies.

Second, land prices react to expectations and thus to the expected subsidy paid. The increase in land prices is thus much larger than the net present value of the subsidy of turbines built. Although redistribution can be achieved by taxing land rents accordingly, the increase in land prices may impact welfare directly if the most productive land buyers face financing constraints (e.g. Hart and Zingales (2013); Moore (2015)). This may be less severe in countries with highly developed financial markets and/or competitive banking sectors. It is however likely to be an important issue if this is not the case and financing constraints are a barrier to market entry (e.g. Rajan and Zingales (1998); Cetorelli and Strahan (2006)).

Unemployment rate	890	0.07	0.05	0.07	0.08	0.05
<i>Tax variables</i>						
Property tax on agricultural land	890	295	266	300	326	50
Property transfer tax	890	3.5	3.5	3.5	3.5	0
Local business tax	890	339	319	332	349	29

Notes: Property tax on agricultural land is the average multiplier in the county. To derive the tax rate the multiplier has to be multiplied with 6%. Local business tax is the average local business tax multiplier in the county. To derive the tax rate the multiplier has to be multiplied with 0.05% before 2008 and 0.035% after 2007. ph stands for per hectare. Sample includes all counties in West Germany in 1998, 2001, 2004 and 2007 that are included in the main estimation analysis.

Source: Author's calculation based on data of the German Weather Service, income tax statistic 1998, 2001, 2004, 2007, operator database 1990-2007, Statistik Lokal and Regional 1998-2007.

B Appendix - Theoretical Framework

In this Appendix, we propose a theoretical model following Titman (1985) to formalize the assumption of the empirical analysis that the expected price of each field of land increases due to the introduction of the REA, independent whether a turbine has been built on a field during our sample period or not. We show this by comparing the price of vacant land in period 1 with the price an investor pays to a land owner in period 1 to build a wind turbine on that land.

Suppose, there are two type of agents, land owners and investors, which live three time periods. Each land owner owns one field at the beginning of period 1. All fields are of equal size and quality and differ only with respect to the wind strength on the field. The agricultural value of land is thus the same for each piece of land and is assumed to be zero.³³ Further, we assume that land owners do not build wind turbines on their own land and that wind turbines do not affect the agriculture return of land. In total there exist K fields.

There are N ($> K$) investors, each of them endowed with one unit of capital at the beginning of period 1. The investors differ in their degree of risk aversion. They maximize their wealth and can choose whether to invest in a one year private capital market investment, yielding return r , or in wind turbines. The wind turbine investment is a two year investment and yields a net-of-costs return π (due to the subsidy) at the end of the investment period. Investment costs are 1. As there are only three periods, wind turbines can only be built in the first two periods. The wind turbine investment is risky in period 1 as wind turbines are a new technology. In the second period, all problems related to the new technology are solved with probability s_H making the wind turbine investment as certain as the private capital market investment. With probability $s_L = (1 - s_H)$, problems still exist and the uncertainty remains. Due to difference in the degree of risk aversion, in period 1 only N_1 ($< K$) sufficiently risk loving investors enter the market. If all problems are solved in period 2, all remaining investors enter the market (N_2) causing excess demand for land, or the number of investors stays the same.

If land owners and investors bargain with each other, land owners bargaining strength is given by β , which is mainly determined by the market conditions. In the case of excess supply of land, β is zero as investors can easily find another suitable piece of land on which to build a wind turbine. In the case of excess demand, β is

³³This assumption is not crucial for the analysis, it only means that the price of land is solely determined by wind turbine profits. The assumption allows us to keep the analysis as simple as possible at the costs of land and capital having different returns.

one due to the low substitution elasticity.

Based on these assumptions, we derive first the price of vacant land k , which is the expected price of land k in period 2 (Titman (1985)). The price of land k ($A_{k,2}$) in period 2 can be derived using a bargaining framework. The outside option of land owners is the agricultural return of land in period 2 and 3, which is set to zero by assumption. Investors' outside option is to invest in the private capital market in period 2 and 3, which has a discounted value of 1. The outcome of the bargaining process for the k field in period 2 is thus given by

$$A_{k,2} = \arg \max \Omega_{k,2} \quad (\text{B.1})$$

with

$$\Omega_{k,2} = \beta_2 \ln(A_{k,2}) + (1 - \beta_2) \ln\left(\frac{\pi_{k,2}}{(1+r)^2} - 1\right) \quad (\text{B.2})$$

$$A_{k,2} = \beta_2 \frac{\pi_{k,2} - (1+r)^2}{(1+r)^2} \quad (\text{B.3})$$

Rearranging the first order condition (equation (B.2)) shows that the price of land equals a share β_2 of the discounted wind turbine profits, after deducting the value of investors outside option $((1+r)^2)$. From the point of view in period 1, it is not clear whether all technical problems related to wind turbines will be solved in period 2 (with probability s_H) or not $(1-s_H)$. If they are solved, β_2 is one as there will be excess supply due to the additional investors entering the market. If they are not solved, β_2 will be zero.

The price of vacant land in period 1 can thus be written as the value of land in the two states of nature in period 2, multiplied with the respective probabilities (see equation B.4). This is nothing other than the net present value of wind turbine profits after deducting investors' opportunity costs multiplied by the probability that there will be more investors than fields available in period 2 (s_H , see equation (B.5)). The whole expression is discounted by one period as it is the land price of tomorrow.

$$p_{k,1}^* = \frac{s_H * \left[\frac{\pi_{k,2}-1}{(1+r)^2}\right] + (1-s_H) * \frac{0}{(1+r)^2}}{(1+r)} \quad (\text{B.4})$$

$$p_{k,1}^* = s_H * \frac{\pi_{k,2} - (1+r)^2}{(1+r)^3} \quad (\text{B.5})$$

In the next step, we show that this price is also paid by an investor to build a wind turbine in period 1. We derive this price using the bargaining framework again. In contrast to period 2, land owners' outside option in period 1 is to reject the offer by the investor and to receive the expected share of profits reaped in the next period, discounted by one period. This outside option value has thus the same value as the price of vacant land. If the investor buys the land today, he earns π in period 2, discounted by two periods, and pays today $A_{k,1}$. The investor's outside option is also to wait, invest in the capital market for one period, and to buy the land and to build a turbine in the next period and invest the remaining capital into the private capital market again. The value of this outside option is thus the discounted capital market investment return for one year ($\frac{r}{(1+r)}$) and the expected net present value of profits of the wind turbine builds in period 2 on the same piece of land. From the point of view in period 1, the investor will receive with probability s_H in period 3 only the capital market return for a wind turbine investment in period 2, with probability $1 - s_H$ he receives the whole surplus of the wind turbine.

The outcome of the bargaining process for the k field in period 1 is given by

$$A_{k,1} = \arg \max \Omega_{k,1} \quad (\text{B.6})$$

with

$$\begin{aligned} \Omega_{k,1} = & \beta_1 \ln(A_{k,1} - s_H [\frac{\pi_{k,2} - (1+r)^2}{(1+r)^3}]) \\ & + (1 - \beta_1) \ln(\frac{\pi_{k,1}}{(1+r)^2} - A_{k,1} - [\frac{r}{(1+r)} + (1 - s_H) \frac{\pi_{k,2}}{(1+r)^3} + s_H \frac{(1+r)^2}{(1+r)^3}]) \end{aligned} \quad (\text{B.7})$$

$$A_{k,1} = s_H \frac{\pi_{k,1} - (1+r)^2}{(1+r)^3} \quad (\text{B.8})$$

The rearranged first order condition, using $\pi_{k,1} = \pi_{k,2}$ and $\beta_1 = 0$ due to excess supply of land, is given by equation (B.8). This is the same expression as derived for the price of vacant land in equation (B.5). Thus, the price of suitable land to build wind turbines increases independent whether a turbine is build or not.

C Appendix - Microsimulation of the Net Present Value of Wind Turbine Profits

In the following, we describe the simulation of wind turbine profits. We explain the microsimulation for the case of simulating the expected net present value of profits of wind turbine built, as this particular application is used to calibrate the model to fit aggregated values. The expected net present value of profits of wind turbines built is also used in the analysis of the impact of agricultural income due to wind turbine subsidies.

The main application of the model is to compute the expected net present value of profits of a county and year representative wind turbine which is used for the estimation of the incidence share. The main difference to the calculation of the expected net present value of profits of a particular wind turbine built is that we used year average technology characteristics for the representative wind turbine and that there is a representative wind turbine in each county and year, regardless whether a turbine has been built in that county and year or not.

The input used for the calculation of the net present value of built wind turbine profits are i) information on the average wind strength in 10 metre and 80 metre above ground, available in a 1 square kilometre raster for the whole of Germany, ii) the location and the technological details of each wind power plant in Germany and iii) the feed in tariff.

Since we only observe the county in which a turbine is located, we map the wind strength data to the county level. More precisely, we map the wind data to the German municipality level and then weight the wind strength on the municipality level with the share of agricultural land in the municipalities to the county level.

The energy produced by a wind turbine depends on the wind strength at the hub height and the technological details of the turbine. For a given roughness parameter (z_o), which accounts for the impact of the shape of the landscape and a given wind strength in one height, the wind strength in every other height can be calculated (see equation (C.1)). Since the average wind strength in 10 metre and 80 metre above ground is given, the roughness parameter is calculated first and then the average wind strength at the hub height.

$$ws_i = ws_j * \frac{\ln(\frac{height_i}{z_o})}{\ln(\frac{height_j}{z_o})} \quad (C.1)$$

$$R_R = \eta * 0.5 * AD * \frac{\pi}{4} * RD_i^2 * \sum P_k W S_{k,R,h_i}^3 \quad (C.2)$$

With the wind strength at the hub height and the technological information of a turbine, the amount of produced energy can be derived using equation (C.2). The efficiency factor of the power plant is given by η and set to 36%³⁴ such that the overall produced energy in 2002 equals the reported produced energy published by the electricity network operators.³⁵ AD is the air density at the hub height. It amounts roughly to $1.2 \frac{kg}{m^3}$. RD is the rotor diameter. Finally, WS stands for the wind strength. Since wind strength affects the return of the wind turbine to the power of three, we approximate the wind strength distribution using the mean wind strength and a Rayleigh distribution, which is a good approximation for the wind strength distribution in Western Europe. In a first step the probability to observe a wind strength of 1, 2, ..., 30 meter per second (m/s) is calculated. It is shown for an average wind strength of 5, 7 and 9 m/s in Figure C.1. Based on the distribution of wind strength in a particular county the amount of produced electricity for each wind turbine is calculated. We further multiply the value per hour with 365 (days) and 24 (hours) to derive the amount per year.

Figure C.2 reports the electricity generated by wind turbines according to our simulation and as published by the network operators for 2000 to 2012.³⁶ Over all the model matches the published data fairly well: Up to 2006 the two lines almost overlap, onwards there are temporary differences.

To derive the stream of revenue for each wind turbine, we determine the feed-in tariff which applies for the year of the connection to the grid.³⁷ For wind turbines built before the REA was introduced we assume that investors expect to receive

³⁴In a robustness check we used the wind strength at the 80th percentile and ended up with an efficiency factor of 0.33. This suggest that our microsimulation is quite accurate as the efficiency factor of wind power plants is between 0.2 and 0.4. The efficiency factor includes the potential breakdown of the plant. Further, it accounts for the fact that plants might not be built at a location with the average wind strength in a county but with a better one. The reader should note that the efficiency factor is different from the capacity factor (ratio of produced to installed capacity) discussed in the literature (e.g. Boccia (2009)). The capacity factor in our study equals the one that can be derived from official publications as our simulation only replicates the aggregated numbers. The efficiency factor we use to calibrate the model is an indicator of how much energy is produced by a particular turbine in relation to the overall kinetic energy available and thus for a given wind strength distribution at a particular location.

³⁵The information is included in the REA statements (<https://www.netztransparenz.de/de/EEG-Jahresabrechnungen.htm>). 2002 is chosen randomly, results are similar when using other years to calibrate the simulation.

³⁶In the year of construction we assumed that half of the yearly energy is feed-in.

³⁷We assume that the year of connection to the grid equals the construction year.

the guaranteed price of 90% of the end-consumer price for three years after the installation of the plant, afterwards we assume that investors expected the average market price for electricity of 3 cent per kWh.

Since the length of the first part of the feed-in tariff under the REA depends on the ratio of the return of the plant to the return of a reference plant defined in the law, we calculated the return of the reference plant using the steps outlined above.³⁸ The hypothetical reference wind power plant is defined as the same plant at a location with 5.5 m/s average wind strength at a height of 30 meter above ground and a roughness parameter of 0.1. Based on the reference plant return, we calculate the years and months the higher first feed-in tariff is paid. After deriving the expected income streams, we simulate the net present value of the future income streams using a discount rate of 3% and a life span of 20 years.

The costs of each wind power plant are assumed to be 650 euros per installed kW capacity based on the survey by Gasch and Twele (2011). They suggest installation costs to be around 530 euros per kW and between 15 and 20% other investment costs, e.g. connection to the grid or baseplate. The investment and related costs are considered by assuming geometric depreciation allowances with a life span of 16 years.³⁹ Further, we assume a ratio of debt financing of 80% with a interest rate of 4.5%. The bank loan is paid back in 8 years. All these parameter choices are based on descriptive statistics of balance sheet and profit and loss statements of wind turbine firms in the database DAFNE (see Appendix D). The equity rate of return is assumed to be 3%.

³⁸The length of the first feed-in tariff is at least 5 years and extended by two months for each 0.75 percent (0.85 for the years 2005 to 2008) of which the produced energy is below 150% of the return of the hypothetical reference wind power plant.

³⁹This was the life span assumed by the tax authorities.

D Appendix - Descriptive Statistics for Wind Turbine Firms in DAFNE

The information on wind turbine firms' depreciation allowances and finance structure are based on descriptive statistics from the DAFNE database. The DAFNE database contains financial statements (mainly balance sheet but for a few firms also income statements) for German firms with a limited liability for the years 2004 to 2012. Since wind turbines at one location are often in single companies and have in most cases limited liability, financial statements are observed for some wind turbine firms. We identify wind turbine firms as follows. In the first stage all firms with *wind* in their company name are identified. From these firms, firms with *operator*, *real estate*, *administration*, or *development* in their company name are excluded. To derive an even finer sample, firms with fixed assets of less than 100,000 euros and firms with a standard deviation of the depreciation allowances above 0.1 are excluded. The first requirement is used as already very small wind turbines with only 133 kWh installed capacity have assets of a value of about 100,000 euros. The second requirement ensures that only "one time wind turbines (parks)" are included and not wind turbine parks to which single wind turbines are added in different years as this would not allow to identify the rate of depreciation allowance.

From roughly 30.000 firms with *wind* in their company name 7.473 are left in the final sample. The number of firms for which the variables of interest are available differ due to data availability. The statistics are shown in Table D.1. They suggest that the rate of depreciation is between 10 and 14% for about 90% of all firms in the sample. This is in line with a geometric depreciation with twice the rate of linear depreciation method rate and a life span of 16 years, which was allowed in Germany for tax purposes between 2001 and 2005. Before and after it was three times the linear depreciation method rate.

Regarding firms' financing behaviour, the overall debt ratio that is available for all firms as well as the ratio of bank liabilities to total assets, available only for a subsample, is reported. The reader should note that due to a different life span of fixed asset and the maturity of loans as well as firms' payout policy the initial debt ratio can only be calculated in the first year. The descriptive statistics suggest a range from 77% to 100% for the overall debt ratio and from 63% to 89% for bank liabilities to total assets. The maturity of debt is similar using overall debt or only bank liabilities and is around 8.5 years. It is calculated using the repayment rates of debt and bank liabilities, respectively. Finally, the interest rate, calculated as

interest payments divided by overall debt and bank liabilities, respectively, is shown in the last four columns. Regardless of whether payments are scaled by current or lagged values, the median interest rate is around 4.5%.

Table D.1: Descriptive Statistics Wind Turbine Firms

	N	p10	p25	p50	p75	p90
Rate of depreciation allowances in %	5,825	0.06	0.10	0.12	0.14	0.21
Debt ratio (DR)	7,473	0.48	0.74	0.91	0.99	1.00
DR year of incorporation	84	0.59	0.77	0.95	1.00	1.00
Bank liabilities to total assets (BL)	1,318	0.49	0.70	0.87	0.96	0.98
BL year of incorporation	18	0.32	0.63	0.81	0.89	0.92
Maturity DR in years	5,849	1.54	5.14	8.41	12.19	19.96
Maturity BL in years	703	3.37	5.98	8.78	11.49	15.98
Interest to debt in %	347	1.38	3.48	4.31	5.06	5.60
Interest to L.debt in %	244	1.46	3.15	3.86	4.56	5.02
Interest to BL in %	287	3.55	4.30	4.92	5.69	8.74
Interest to to L.BC in %	173	3.35	3.84	4.44	5.19	9.27
