On the interpretation of non-cognitive skills – what is being measured and why it matters

John Eric Humphries and Fabian Kosse
SOEPpapers on Multidisciplinary Panel Data Research at DIW Berlin

This series presents research findings based either directly on data from the German Socio-Economic Panel study (SOEP) or using SOEP data as part of an internationally comparable data set (e.g. CNEF, ECHP, LIS, LWS, CHER/PACO). SOEP is a truly multidisciplinary household panel study covering a wide range of social and behavioral sciences: economics, sociology, psychology, survey methodology, econometrics and applied statistics, educational science, political science, public health, behavioral genetics, demography, geography, and sport science.

The decision to publish a submission in SOEPpapers is made by a board of editors chosen by the DIW Berlin to represent the wide range of disciplines covered by SOEP. There is no external referee process and papers are either accepted or rejected without revision. Papers appear in this series as works in progress and may also appear elsewhere. They often represent preliminary studies and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. A revised version may be requested from the author directly.

Any opinions expressed in this series are those of the author(s) and not those of DIW Berlin. Research disseminated by DIW Berlin may include views on public policy issues, but the institute itself takes no institutional policy positions.

The SOEPpapers are available at http://www.diw.de/soeppapers

On the interpretation of non-cognitive skills – what is being measured and why it matters

John Eric Humphries (University of Chicago)*
Fabian Kosse (University of Bonn)†

November 2016

Abstract

Across academic sub-fields such as labor, education, and behavioral economics, the measurement and interpretation of non-cognitive skills varies widely. As a result, it is difficult to compare results on the importance of non-cognitive skills across literatures. Drawing from these literatures, this paper systematically relates various prototypical non-cognitive measures within one data set. Specifically, we estimate and compare several different strategies for measuring non-cognitive skills. For each, we compare their relative effectiveness at predicting educational success and decompose what is being measured into underlying personality traits and economic preferences. We demonstrate that the construction of the non-cognitive factor greatly influences what is actually measured and what conclusions are reached about the role of non-cognitive skills in life outcomes such as educational attainment. Furthermore, we demonstrate that, while sometimes difficult to interpret, factors extracted from self-reported behaviors can have predictive power similar to well established taxonomies, such as the Big Five.

Keywords: non-cognitive skills, personality, preferences, educational success.

JEL-Classification: J24, I20, D03, D90

1 Introduction

Many traits, skills, and abilities matter for success in life.\footnote{The literature uses the expressions traits, skills and abilities to describe unobserved individual heterogeneities. Some papers use traits to describe immutable characteristics of individuals, while using skills when referring to malleable characteristics. For the most part, including this paper, these terms are used interchangeably.} Yet, the underlying dimension and classification of these traits are widely contested within economics and across the social sciences. In economics, “non-cognitive” skills have recently become very popular in applied research, but there is little agreement on what these types of skills represent. In labor economics, non-cognitive skills are usually seen as a broadly defined second dimension of individual heterogeneity (next to cognitive skills). In the education and early childhood intervention literatures, non-cognitive skills are broadly categorized as skills not captured by standardized tests and are commonly measured by observing behavior. In economic psychology and behavioral economics, non-cognitive skills are seen as a superordinate concept summarizing various specific concepts (i.e. economic preferences such as time and risk preferences), as well as personality measures (as the Big Five). Overall, across sub-fields, and across papers within sub-fields, the measurement and interpretation of non-cognitive skills varies widely due to the different motives and available data sources.

The aim of this paper is to compare several different strategies for measuring non-cognitive skills and to decompose and interpret their relative effectiveness in predicting educational success. Using data from the youth survey of the German Socio-Economic Panel (GSOEP), we construct four stylized factors based on measures from the previous literature and relate the different estimates of non-cognitive skills to each other and to established taxonomies. To the best of our knowledge, this is the first paper that systematically relates the various non-cognitive measures used in the literature within one data set. We also contribute to the literature on skills in the education context and evaluate how the different non-cognitive skill constructs relatively perform in predicting educational success.\footnote{For a paper that focuses on the relation between psychological personality measures and economic preference measures see Becker et al. (2012).} We shed light on what previous papers have measured when using different methods to generate proxies of non-cognitive skills.
and show that the construction of the non-cognitive factor greatly influences what is actually measured and which conclusions are reached about the role of non-cognitive skills.

**Measuring non-cognitive skills:** Different sub-fields tend to have different intentions when constructing non-cognitive factors, which may explain the lack of standardization. Researchers sometimes rely on formal models to determine the nature and dimension of the skills to be estimated. At other times, researchers may only be concerned with fully capturing and controlling for pre-existing differences. In the latter case, the researchers may not care about interpretation of the extracted skills, as their only aim may be to span as much of the underlying multidimensional heterogeneity as possible. Below we review three literatures that study non-cognitive skills, highlighting differences in their methodologies for measuring non-cognitive skills and their motivations for including them in their analyses.

In labor economics, a one dimensional skill or ability has been used to differentiate workers (Becker, 1964; Herrnstein and Murray, 1994; Neal and Johnson, 1996; Carneiro, 2002). More recent research has used a two-factor framework which usually consists of a “cognitive” component and a “non-cognitive”, “socio-emotional” or “personality” component which is an aggregate of skills or traits other than cognition that are important determinants of educational and labor market outcomes. (Heckman and Rubinstein, 2001; Heckman et al., 2006). For historical reasons, the “non-cognitive” component has been constructed from measures included in social surveys such as the National Longitudinal Survey of Youth 1979 (NLSY79). Commonly, these are one dimensional constructs combining self-reported measures of self-esteem, locus of control, or other similar measures. When labor-economists extract multi-dimensional heterogeneity, they commonly aim to simply correctly control for pre-existing differences, and they do not focus on the interpretation of the additional traits.³

Non-cognitive skills have also become important components of the education economics and early childhood intervention literature. Some early interventions were found to have no lasting

---

³See, for example, Keane and Wolpin (1994) and the related literature on latent types. This literature uses types to span a potentially multi-dimensional unobservable component of individuals, but generally do not focus on what skills, traits, or differences the types are capturing.
effect on test scores, yet still improved later-life performance of participants. Similarly, research on the GED high school equivalency exam found that GED certificate recipients performed similarly to high school graduates on achievement tests, yet performed worse later in life. The research on early interventions and the research on the GED raised questions about what skills other than cognition were being formed by education. Looking beyond test scores, researchers in education economics have turned to behaviors measurable in their data, such as behavioral issues, absences, engagement, and teacher reports (see Heckman et al. (2013a)).

More recent research in economic psychology and behavioral economics have taken a somewhat different approach. This literature uses the term “non-cognitive” (or soft) skills as a generic term for a whole set of constructs to differentiate individuals (e.g. Borghans et al., 2008b; Koch et al., 2015). The most frequently used constructs are either key economic variables, such as preferences for risk and time, or, are borrowed from psychology as, e.g., the Big Five personality inventory (Costa and McCrae, 1992). This work has focused on precisely measuring and describing multiple facets of personality and preferences, using incentivized laboratory experiments or extensive questionnaire batteries. However, these precise measures are often not connected to information about later-life outcomes. Exceptions that connect (incentivized) preference measures and real-life outcomes are e.g. Burks et al. (2015, 2012), Golsteyn et al. (2014), Sutter et al. (2013), Rustichini et al. (2012) and Chabris et al. (2008). Burks et al. (2015) is most closely related to this paper and considers the relation between education outcomes, personality measures and economic preferences.

All three strands of literature concur that skills other than cognition are important in explaining heterogeneity in behaviors and outcomes between people. Research across these fields shows the importance of non-cognitive skills, but little consensus exists on what is being measured.

---

4 For an overview about the concepts and for a discussion on using the term “non-cognitive” in this context see Borghans et al. (2008a).
5 For an overview and discussion see e.g. Becker et al. (2012)
6 The five personality dimensions are are labeled as conscientiousness, agreeableness, neuroticism, openness, and extraversion.
7 There are a number of overviews of the literature on non-cognitive skills: Koch et al. (2015) on behavioral economics of education, Thiel and Thomasen (2013) on models and measurement, Gutman and Schoon (2013) on effects on various outcomes and Brunello and Schlotter (2011) on effects on educational and labor market outcomes. For an early overview focusing on labor market returns see Groves (2005). Almlund et al. (2011) refer to cognitive and non-cognitive skills and summarize empirical results.
and what matters. Due to data availability, the labor and education literature have focused on survey questions and reported early-life behaviors to construct a single measure of non-cognitive skills. Heckman et al. (2006) state in this context “we choose these measures because of their availability in the NLSY79. Ideally, it would be better to use a wider array of psychological measurements and ... to connect them with more conventional measures of preference parameters in economics.” (p. 429).

While cognitive ability clearly maps into the concept of intelligence, the interpretation of the non-cognitive factor depends on the various measures and behaviors used in its construction. Non-cognitive factors are generally difficult to interpret and do not easily map into pre-existing taxonomies such as economic preferences or personality traits. As different papers use different constructions of non-cognitive skills, it is difficult to reach consilience on the importance of non-cognitive skills on educational and labor market outcomes.

We provide a first step in reconciling the evidence on non-cognitive skills by directly comparing different measures of non-cognitive skills. Specifically, we use new data from the Youth Survey of the German Socio-Economic Panel (SOEP, 2013; Wagner et al., 2007) to compare several prototypical non-cognitive constructs drawn from the different approaches taken in the different fields. The GSOEP Youth Survey is particularly suited for this task as it contains measures of IQ, schooling-related behavior, social behavior, personality measures, and measures of economic preferences. Using these measures, this paper constructs four stylized models of cognitive and non-cognitive skills in order to interpret how different constructions of non-cognitive skill may result in different conclusions about the relative importance of non-cognitive skills in educational and economic outcomes. These models are compared to a baseline model that includes Big Five personality traits, economic preferences, and IQ. We use Big Five personality traits, economic preferences, and IQ as our baseline model as these measures are established taxonomies with deep roots in the personality psychology, cognitive psychology, and economic literature.\(^8\) As shown by Becker et al. (2012), the Big Five personality traits and economic

\(^8\)Admittedly, there is no proof that the Big Five personality trait, economic preferences, and IQ span the full set of latent traits. Instead, we focus on these measures as they are widely studied and may be easier to directly interpret.
preference parameters permit a wide range of individual heterogeneities and complement each other in predicting life outcomes.

We find that the various stylized non-cognitive factors are not strongly related to each other, and in fact some have negative correlations. The differences between the non-cognitive factors can be explained by different correlations with the traits of our baseline model. For example, all four of our non-cognitive factors are positively correlated with conscientiousness and patience, and some are positively correlated with willingness to take risk and extraversion, while others are negatively correlated. In this paper we also consider the role of skills in determining educational success (measured by high school GPA) and show that different non-cognitive factors have different explanatory power on educational outcomes. As a second analysis, we also demonstrate that observed behaviors can be used to extract latent factors with approximately the same amount of predictive power as traditional survey-based taxonomies such as the Big Five or economic preferences, though the interpretation of the factors becomes much more difficult. Different policy conclusions can be reached depending on which measurement system on non-cognitive skills is used.

2 Data and measures

Our analysis uses data from the German Socio-Economic Panel (SOEP, 2013), a large panel data set that is representative for the German population which was started in 1984. Today it consists of more than 20,000 individuals in more than 10,000 households, for details see Wagner et al. (2007). Since 2001, all young people in the sample receive a special “Youth Questionnaire” at age 17. Starting in the year 2006, the youth questionnaire measures preferences and personality and includes an IQ test. The answers and measures collected in in the youth questionnaire are our main source of information. We complement this information with data about consumption behavior from the main questionnaire of the GSOEP. Our main analysis uses data on more than 1,300 adolescents interviewed at age 17 in the years 2006 to 2012.

9These information were usually collected one or two years after the youth questionnaire, for details see below and Wagner et al. (2007).
Using the GSOEP, we are able to construct quality measures of personality traits, risk and time preference, and IQ. The Big Five is measured using a validated 15-item questionnaire (Gerlitz and Schupp, 2005) that is commonly used in empirical personality research (see, e.g., Becker et al., 2012). Risk preference is measured by the question “How do you see yourself: Are you generally a person who is fully prepared to take risks, or do you try to avoid taking risks?” Answers were given on an 11-point scale, where zero corresponds to “unwilling to take risks” and 10 corresponds to “fully prepared to take risks.” This question has been studied in various papers and is highly correlated with incentivized experimental measures and revealed behavior (see, for example, Dohmen et al., 2011). To measure time preference, the participants rated how strongly they agree with the two statements “I abstain from things today to be able to afford more tomorrow” and “I prefer to have fun today and don’t think about tomorrow” (reversed) on a 7-point Likert scale. We construct our measure of time preference by summing the standardized responses. The resulting score is well correlated with incentivized experimental measures of time preference.\footnote{Using data of Vischer et al. (2013) indicates a highly significant correlation (p<0.001, N=965).} To measure cognitive skills, the participants took part in a validated short version of the well-established “I-S-T 2000 R” (Amthauer et al., 2001), covering all three subsets which are verbal, numerical, and figural abilities (for details see Solga et al., 2005).

Below, we estimate four stylized two-factor models. Each model constructs a non-cognitive factor using different reported behaviors or questionnaire responses. The different non-cognitive factors are chosen to be similar to measurement systems used in applied labor economics and the economics of education literature. For all four models, the cognitive factor is uniformly constructed from three IQ sub-tests.\footnote{Some papers use achievement tests to measure cognition rather than IQ. As shown in Borghans et al. (2011), achievement tests may capture traits other than IQ. As the GSOEP does not include achievement test scores, we cannot consider variation on this dimension.} Each factor model assumes there are two factors and each model is estimated by maximum likelihood. As in standard factor analysis, we assume that the covariance between a set of measures can be fully explained by a low-dimensional vector of unobservables. In this case, we assume the unobservables are distributed as a correlated bi-variate normal distribution. In the web-appendix, we relax the strong assumption...
of normality and estimate factor scores using the minimum distance estimator. As expected
from a less efficient estimator, standard errors are somewhat larger when using minimum
distance estimation, but the point estimates are very similar to those obtained using maximum
likelihood. In order to identify and interpret the factors, we assume that the IQ measures only
load on the cognitive factors, while the non-cognitive measures load only on the non-cognitive
factor. No restrictions are placed on the correlations between the factors. We normalize the
variance of both factors to unity, pinning down the scale of each unobservable.12 From our
estimated factor model, we use maximum likelihood to predict individual factor scores (for an
overview see Heckman et al., 2013c), which are further standardized to have a mean of zero
and a standard deviation of one.

For each two-factor system, a different set of behaviors or responses is used to identify the
non-cognitive factor. For an overview see Table 1. Model 1 (NC-LOCUS) uses responses
on a 10-item Locus of Control questionnaire (Rotter, 1966) and a single item self-esteem
questionnaire (Robins et al., 2001), as has been done in work using the National Longitudinal
Survey of Youth 1979, such as in Heckman et al. (2006). Model 2 (NC-ENGAGEMENT) uses
participation in extra-curricular activities, time used on productive leisure time engagement,
and number of close friends.13,14 Model 3 (NC-RELATIONS) uses the quality of relations to
parents and friends covering topics such as arguments and fights as well as constructive problem
solving, love and bonding15,16, and the number of close friends. Model 4 (NC-BEHAVIORS)
uses reported behavior on drinking, smoking and eating habits17, and how often the individual

12Given we have more than five measures for our correlated two-factor model, and at least three dedicated
measures in each of our models, our factor models are non-parametrically identified, as laid out in Williams
(2013).
13Information is based on time-use questionnaires. Individuals were asked about their general engagement in
school-based extra-curricular activities and indicated their degree of involvement (5-point Likert scale) in a list
of (leisure time) activities.
14For example, Borghans et al. (2008c) use similar engagement measures as a measure of non-cognitive skills.
15Individuals rated the frequency of respective situations on a 5-point Likert scale.
16For example, see Heckman et al. (2013c) for a paper that also uses reported relations as a measure of
non-cognitive skills.
17Individuals rated on 4-point Likert scales how much they follow a healthy diet and how often they consume
beer, wine, spirits, and long drinks. They also indicated if they smoke or not.
argues with their parents or best friend. BASE is the label of the baseline model composed of the Big Five and economic preferences.

Across the four models, we believe that we have embodied many of the different definitions of non-cognitive skills found in literatures from different disciplines. Tables 2 and 3 give an overview of which measures are used to capture non-cognitive skills in a number of top papers. The last column relates the constructions used in these various papers to our stylized models.

---

18 There are only around 750 observations for this measure as it uses variables which are collected in later questionnaires, which have not yet been answered by all those who have answered the age 17 questionnaire.

19 Papers using self-reported behaviors to construct non-cognitive factors are common, see for example Heckman et al. (2013b).

20 Some papers that study cognitive and non-cognitive skills do not explicitly use a two-factor structure (for example, Cobb-Clark and Tan (2011); Farkas (2003); Rustichini et al. (2012); Lleras (2008)). Rather, these papers include a number of measures which they believe serve as proxies for non-cognitive skills and discuss how these measures affect the outcome of interest.

3 Results

In order to structure and guide the following analysis we present a small descriptive model. Let $y_i$ represent the outcome of interest of individual $i$ and assume the following additive-separable and linear-in-parameter model:

$$ y_i = \sum_{j=1}^{J} \beta_j NC_j^i + \beta_C C_i + u_i $$

(1)

As described in the previous section we will always use the same cognitive factor $C$ and combine it with various single or multiple non-cognitive factors $NC_j^i$. $u$ is the idiosyncratic error.

When we refer to the stylized two-factor models, there is only one non-cognitive factor ($J = 1$) which is NC-LOCUS (NC-L), NC-ENGAGEMENT (NC-E), NC-RELATIONS (NC-R) or NC-BEHAIORS (NC-B), respectively. When we refer to the baseline model (BASE), the term “non-cognitive” is used as a superordinate concept summarizing various specific concepts recently used in behavioral economics such as economic preferences as well as personality measures. Therefore, when using the baseline model, there are seven non-cognitive factors ($J = 7$) which are conscientiousness, agreeableness, neuroticism, openness and extraversion, as well as, time and risk preference.\(^\text{21}\)

The empirical analysis is structured in three steps. First, to analyze what is measured by the different stylized non-cognitive factors, we relate them to each other and to the baseline model. We show that the extracted non-cognitive factors have only moderate (sometimes negative) correlations across models and have plausible but varying correlations with measures of the Big Five personality traits and economic preferences. We decompose each non-cognitive factor by regressing each non-cognitive factor on the covariates from the baseline model (IQ, Big Five

---

\(^{21}\)See Almlund et al. (2011) for a more detailed model of agent behavior. In that paper, they highlight that the distinction between test scores and behaviors is somewhat arbitrary, in that both are observed responses to a particular action. In their model they highlight that the response will depend on underlying latent skills, but may also depend on incentives for the task and the environment in which the tasks in administered.
personality traits, time preference, and risk preference). We find that different personality traits and economic preferences play important roles in the different constructions of the non-cognitive factors.

Second, we use the descriptive model presented in Equation (1) to evaluate how much the predictive power of non-cognitive skills changes when using different constructions of non-cognitive skills. Specifically, we compare regressions of GPA on each of our two-factor models and on our baseline model. We find that the different non-cognitive factors vary widely in their ability to explain outcomes; therefore, different constructions of the non-cognitive factor lead to different conclusions about their relative importance. The baseline model outperforms every two-factor model, and the stylized non-cognitive factors from the two-factor models add little or no additional explanatory power to the baseline model.

Third, we evaluate the overall ability of behavioral measures to predict GPA in comparison to the baseline model consisting of questionnaire-based taxonomise. We use all behavioral measures (input to NC-E, NC-R, NC-B) to perform an exploratory factor analysis and to predict new factors. We use these new factors to predict educational success and show, while difficult to interpret, they have similar explanatory power as the baseline model.

3.1 Relations of the stylized factors and the baseline model

As presented in Table 4, the correlations between the four non-cognitive factors are quite low. The correlation between the different non-cognitive factors ranges between -0.12 and 0.21. Interestingly, the correlation between NC-LOCUS and NC-BEHAVIORS is negative while the correlations between NC-RELATIONS and NC-LOCUS and between NC-RELATIONS and NC-BEHAVIORS are positive. This suggests that each factor may be capturing different aspects of a vector of unobservable non-cognitive characteristics. Looking at the lower half of Table 4 indicates that all stylized non-cognitive factors are significantly positively correlated with conscientiousness and patience. Personality psychology would interpret this as “construct validation” for our non-cognitive factors. Furthermore, different non-cognitive factors are correlated with different aspects of the Big Five, economic preference parameters, and IQ.
Moreover, NC-LOCUS is also positively correlated with IQ and has a strong negative correlation with neuroticism. NC-ENGAGEMENT has lower correlations than the previously discussed factors, but is correlated most with risk, openness, and extraversion. NC-RELATIONS is highly correlated with many of the other factors. It is positively correlated with agreeableness and openness. NC-BEHAVIORS is positively correlated with both agreeableness and neuroticism but negatively correlated with willingness to take risk, extraversion, and IQ.

Table 7 regresses the cognitive factor and each of the (standardized) non-cognitive factors on the Big Five personality traits and economic preferences. This table provides similar evidence as Table 2, but now considers partial correlations between parameters in the baseline model and the factors. For each factor, we regress the factor on Big Five personality traits, IQ, time preference, and risk preference. Overall, we find that the partial correlations confirm the relationships found in Table 2. As found in the psychology literature, IQ is most strongly correlated with openness. Extraversion and neuroticism are negatively correlated with IQ.

---

22 Each model has a uniquely estimated cognitive factor as the factors in each model are estimated jointly. Yet, the cognitive factor is estimated using the same measures across models and have correlations of nearly unity.
while time preference is positively correlated.

All four of the non-cognitive constructs have positive partial correlations with conscientiousness. These relationships are statistically significant, except in the specifications regarding NC-ENGAGEMENT and NC-RELATIONS, where conscientiousness is not statistically significant once we control for time preference.\(^{23}\) Evaluating the non-cognitive factors according to the R-squared by personality and preference measures reveals notable differences. While Big Five personality traits and economic preference measures can explain more than 13% of the variation in NC-LOCUS, they explain only about 5% of the variation in NC-Engagement.\(^{24}\)

The analysis in Table 8 and 9 focus on time and risk preferences. We regress time and risk preferences on on the the stylized 2-factor models, the Big Five personality measures and IQ, as well as, combinations of the 2-factor models and the Big Five. The results of this multivariate regression analysis largely confirm the results of the raw correlation analysis presented in Table 4. Time preference (patience) is partially positively correlated with all non-cognitive factors, as well as, with cognitive skills and conscientiousness. For risk preference (willingness to take risk) we find positive significant partial correlations with NC-LOCUS and NC-ENGAGEMENT, no significant relation to NC-RELATIONS and negative significant partial correlations with NC-BEHAVIORS.

### 3.2 Educational outcomes: stylized factors and the baseline model

Previous literature provides evidence for the importance of school performance and educational decisions for later life outcomes (see, e.g., Heckman et al., 2013b). While there is a broad consensus that non-cognitive traits play a critical role in the determination of these outcomes and decisions (see discussion in Almlund et al., 2011), little is known about the actual drivers behind the abstract concept of non-cognitive traits.

In this section, we compare the four stylized two-factor models and the baseline model regarding

\(^{23}\)Time preference and conscientiousness are closely related concepts and have a correlation of 0.31 in our sample.

\(^{24}\)Tables report R-squared. Given the low number of parameters, the R-squared and adjusted R-squared agree to three or more decimal places.
predictive power. Tables 5 considers how the different two-factor models predict high school GPA. We regress GPA on each of the four stylized two-factor models as well as on our baseline model of personality traits and economic preferences. In the last four columns we combine each two-factor model without the baseline model to check if the extracted non-cognitive factor has predictive power beyond the baseline model. The dependent variable in Table 5, GPA, can range from zero to four and is coded such that higher values indicate better performance.\textsuperscript{25} GPA is measured at age 17 and calculated as the average of grades in mathematics, German, and first foreign language. The distribution is displayed Figure 1. In the German grading system, the best and the worst grade are relatively rarely used and so we observe little to no censoring at the bottom or the top of the GPA distribution. The mean (standard deviation) in our sample is 2.08 (0.71).

OLS regressions indicate that cognitive ability predicts GPA, but so do all of the non-cognitive factors (though the loadings vary in size and significance). The loadings on the non-cognitive factor vary, but even the largest is less than one third the size of the loading on cognition.\textsuperscript{26} Comparing the the predictive power of the two-factor models to a one-factor model which only consists of the cognitive factor (Cog-only), indicates that the non-cognitive factors of the stylized two-factor models add little explanatory power in terms of R squared. In the baseline model, cognition and conscientiousness are positively correlated with GPA while risk preference and agreeableness are negatively correlated. The coefficient on conscientiousness is approximately three quarters of the size of the coefficient on cognition. The baseline model explains six percent more of the variance than the two-factor models.\textsuperscript{27} No substantial additional explanatory power over the baseline model alone is observed when we include the different non-cognitive factors in the baseline model. In general, we find similar results regarding size and significance if we control for gender, urban status, residence in Eastern

\textsuperscript{25}In the German grading system, theoretically, one is the best grade and six is the worst grade. Both, 5 and 6, indicate failing. The grade 6 is hardly ever used. The worst average grade (in the German system) that we observe in the data is 5. The grades are recode in a way that 1 translates to 4, 2 to 3, 3 to 2, 4 to 1 and 5 to 0.

\textsuperscript{26}All skills are standardized to have a mean of zero and a standard deviation of one.

\textsuperscript{27}Note that personality and economic preference have substantial predictive power and explain 10.6% of the variance in GPA without the inclusion of IQ.
Figure 1 Distribution of GPA. Higher values indicate better performance, \( N = 1333 \).

Germany and the student’s educational tier\(^{28}\) or if we use the minimum distance estimator to estimate the non-cognitive factors (see Table 10 and 11).

In sum, this horse race analysis shows that conclusions regarding the importance of the non-cognitive factor strongly depend on the measurement system. If we just consider the non-cognitive factors from the stylized two-factor models, we would, e.g., conclude that the cognitive factor is much more important than the non-cognitive factor in predicting GPA. In contrast, if we consider the baseline model, including validated measures on conscientiousness, we would conclude that cognitive and non-cognitive skills are of similar importance in predicting GPA.

\(^{28}\)The secondary education system in Germany consists essentially of three tracks (low, medium, high) which are supplemented by comprehensive schools and vocational school.

Notes: The table shows OLS estimates of GPA on one of the four constructed 2-factor models, our baseline model, or combined models; Standard errors in parentheses. NC-L is based on the Rotter’s Locus of control. NC-E is based on engagement behavior, NC-R is based on self-reported relationships, and NC-B is based on self reported risky behaviors.  * p < 0.10, ** p < 0.05, *** p < 0.01.
3.3 Educational outcomes: ad hoc factors extracted from behaviors and the baseline model

In the previous section the main intention was to use interpretable stylized factors to predict outcomes. In the last step of the analysis, we give up the structure concerning the non-cognitive factors. We focus on revealed behavior and use the engagement, relations and behavior related input data of NC-E, NC-R and NC-B to perform an exploratory factor analysis and to predict new ad hoc non-cognitive factors. These ad hoc factors are harder to interpret but capture the heterogeneities concerning the input measures optimally. We use these new factors to predict educational success and show that they have similar explanatory power as the baseline model.

Performing an explanatory factor analysis on the standardized behavior input measures of NC-E, NC-R and NC-B yields six factors according to Horn (1965). The labeling concerning the factors resulting from an exploratory factor analysis is always arbitrary; therefore, we just label them as non-cognitive factor 1 to 6. The structure of the factor loadings suggests that ad hoc factor Noncog1 (more or less) corresponds to NC-B, Noncog2 corresponds to NC-R and Noncog3 to NC-E.

Due to the use of exploratory factor analysis, the sample is restricted to observations for which all variables are available. In Table 6 we compare the predictive power of the six ad hoc NC factors resulting from the exploratory factor analysis and the baseline model. In column 1 GPA is regressed on the six ad hoc NC factors. For comparison, in column 2, GPA is regressed on the Big Five personality traits and economic preferences (the baseline model). While the R-squared is slightly higher for the baseline model that uses the established taxonomies, the Bayesian information criteria (BIC) that accounts for the number of used coefficients indicate a slightly better fit for the ad hoc model using information on behavior in column 1.

Column 3 and 4 repeat the estimations of column 1 and 2 but use cognitive skills as additional

\(^{29}\)NC-L consists of items of validated Locus of Control and Self-esteem questionnaires (see section 2) and therefore we are intentionally not using the items to extract ad hoc non-cognitive factor from the revealed behavior data.

predictor. As expected, the R-squared in both models increases remarkably. The increase is weaker in the ad hoc model which indicates that the behavioral measures also includes information on cognitive skills, leading the overall R-squared to be somewhat smaller than that of our preferred model.

4 Conclusion

This aim of this paper is to compare several different strategies for measuring non-cognitive skills and to decompose and interpret their relative effectiveness in predicting educational success. Using data from the youth survey of the GSOEP, we construct four stylized factors based on measures from the previous literature and relate the different estimates of non-cognitive skills to each other and to established taxonomies. The correlation between the different non-cognitive factors varies greatly, ranging between -0.12 and 0.21. Given the heterogeneity among the different non-cognitive factors, we compare them with a baseline model that contains personality traits and economic preference parameters. While all stylized factors are positively correlated with conscientiousness and patience, their relationships to other dimensions vary substantially.

In the context of educational outcomes, we find that the baseline model outperforms all of the 2-factor models in terms of predictive power. Moreover, there is heterogeneity among the relevance of the different non-cognitive factors. In general, the higher the correlation with traits from our baseline model, such as conscientiousness and time preference, the higher their predictive power concerning educational outcomes. When we perform an exploratory factor analysis where we remove the structure concerning the non-cognitive factors and capture the information of the behavioral input measures optimally, we find similar explanatory power for baseline model and non-cognitive factors. This suggests that, if a researcher simply cares about proxying for unobserved heterogeneity, rich sets of behaviors may perform as well as

30While this study focuses on the late adolescence, in principle, we expect the general pattern to also hold for adults. Cognitive skills have been shown to have relatively stable rank orderings by the middle of childhood. For many non-cognitive skills, rank-order stability peaks after age 50. For a detailed discussion see Borghans et al. (2008a).
questionnaires and taxonomies developed specifically for the task.

This paper demonstrates that building a single non-cognitive factor from behavioral or survey measures still provides useful insights, but may under-predict the correlation with the larger set of non-cognitive traits and outcomes. Furthermore, this paper provides a road map of which personality traits and economic preferences may be measured by various two-factor models (inspired by recent papers). This decomposition can serve as a first step towards integrating findings from studies that use different measurement systems for non-cognitive factors. In summary, this paper suggests that many two-factor models may be underpredicting the importance of non-cognitive skills compared to models which use richer sets of (validated) measures. Moreover, papers that reach different conclusions about the importance of non-cognitive skills may do so because of differences in how their non-cognitive factors were constructed.

By understanding what different non-cognitive constructs measure, we can better understand which skills matter for success in life. For example, knowledge about specific traits that drive educational success could lead to more targeted interventions as e.g. Schunk et al. (2016) or Alan et al. (2015). Ultimately, understanding what various constructs measure allows us to create consilience across the various studies, creating the potential for improved policy making.
